Abstract: Opioid receptors are found in the Central Nervous System (CNS) and are classified as mu (µ), kappa (κ), delta (δ) and sigma (σ) opioid receptors. Opioid receptors belong to the large family of G Protein Coupled Receptors (GPCRs), and have diverse and important physiological roles. The aim of the present review is to discuss the roles played by opioid receptors, their agonists and antagonists in health and disease conditions. Opioid receptors are not uniformly distributed in the CNS and are found in areas concerned with pain, with the highest concentration in the cerebral cortex, followed by the amygdala, septum, thalamus, hypothalamus, midbrain and spinal cord. Activated delta opioid receptors are coupled to Gi1 while activated mu opioid receptors are coupled to Gs in neuroblastoma cells. Mu opioid receptors are activated by mu receptor agonists and are coupled through the Gαs and Gq,α. Both mu and kappa opioid receptors are coupled via both Gi and Gq in HEK 239 cells. The opioid receptors are important targets for thousands of pharmacological agents. GPCRs typically require activation by agonists for their signalling activity to be initiated but some of the GPCRs may display basal or spontaneous signalling activity in the absence of an agonist. The stimulation of these receptors triggers analgesic effects and affects the function of the nervous system, gastrointestinal tract and other body systems. Hundreds of analogs of opioid peptides have been synthesized in an effort to make the compounds more active, selective, and resistant to biodegradation than the endogenous ligands. All these modifications resulted in obtaining very selective agonists and antagonists with high affinity at mu-, delta- and kappa-opioid receptors, which are useful in further studies on the pharmacology of opioid receptors in a mammalian organism.

Key words: Delta opioid, G-protein coupled receptors, κ-Opioid, µ-Opioid, opioid agonists, opioid antagonists, opioid receptors

INTRODUCTION

The term opioid refers to any natural or synthetic drugs that have morphine-like activity. They are classified as natural, semi-synthetic and synthetic opioids. Examples of natural opioids are morphine, codeine noscopine; semi-synthetic are heroin, oxymorphone and hydromorphone, while the synthetic opioids are methadone, morphinians and benzamorphans (Piestrzeniewicz et al., 2006). Opioid receptors are found in the Central Nervous System (CNS) and are classified as mu (µ), kappa (κ), delta (δ) and sigma (σ) opioid receptors. Opioid receptors are not uniformly distributed in the CNS but are found in areas concerned with pain receptors, with the highest concentration in the cerebral cortex, followed by the amygdala, septum, thalamus, hypothalamus, midbrain and spinal cord (Raynor et al., 1996; Chaturvedi et al., 2000). The mu receptor has been shown to be high in areas of pain perception and in the medulla, especially in the area for respiration (Reisine and Bell, 1993; Reisine and Brownstein, 1994; Massotte and Kieffer, 1998; Hasbi et al., 2000).

The opioid receptors (mu, delta, and kappa) belong to the large family of GPCRs and have diverse and important physiological roles (Piestrzeniewicz et al., 2006; Rhim and Miller, 1994). Laugwitz et al. (1993) have shown that activated delta opioid receptors are coupled to Gi1 while activated mu opioid receptors are coupled to Gs in neuroblastoma cells (SH-SY5Y). Mu opioid receptors have been shown to be activated by mu receptor agonists and are coupled through the Gαs and Gq,α in human embryonic kidney (HEK 239) cells (Saidak et al., 2006). Tso and Wong (2000), have shown that both mu and kappa opioid receptors are coupled via both Gi and Gq in HEK 239 cells. The opioid receptors are important targets for thousands of pharmacological agents (Hasbi et al., 2000; Wang et al., 2007). The stimulation of these receptors triggers analgesic effects and affects the function of the nervous system, gastrointestinal tract and other body systems.
systems (Piestrzeniewicz et al., 2006). The discovery of opioid peptides (including delta-selective enkephalins, kappa-selective dynorphins, and mu-selective endomorphins), which are endogenous ligands of opioid receptors, initiated their structure-activity relationship studies (Fichna et al., 2006).

Piestrzeniewicz et al. (2006) have shown that in the last 30 years, hundreds of analogs of opioid peptides have been synthesized in an effort to make the compounds more active, selective, and resistant to biodegradation than the endogenous ligands. Different unnatural amino acids, as well as cyclisation procedures, leading to conformationally restricted analogs, were employed. All these modifications resulted in obtaining very selective agonists and antagonists with high affinity at mu-, delta-, and kappa-opioid receptors, which are extremely useful tools in further studies on the pharmacology of opioid receptors in a mammalian organism (Piestrzeniewicz et al., 2006; Xiong et al., 2007). GPCRs typically require activation or stimulation by agonists for their signalling activity to be initiated but Wang et al. (2007), have shown that some of the GPCRs display basal or spontaneous signalling activity in the absence of an agonist. This basal or spontaneous signalling activity is also called constitutive activity (Wang et al., 2007; Piiper and Zeuzem, 2004).

As mentioned, opioids exert their biological activity through the activation by GPCRs, and their effects can be blocked by receptor antagonists. Opioid antagonists with different inverse agonist properties have different effects in precipitating withdrawal in acute morphine dependent mice, and constitutive opioid receptor activation is critically involved in acute opioid withdrawal (Freye and Levy, 2005; Wang et al., 2007; Xiong et al., 2007). It has been shown that the pharmacological properties and activities of the three opioid receptor classes are distinct and can be clearly differentiated (Raynor et al., 1996). Opioid receptors have high affinity for both agonists and antagonists. DAMGO and its antagonists do not bind to delta or kappa receptors, and morphine and its derivatives are much less potent at the delta or kappa receptors. All three opioid receptors are sensitive to the antagonist naxlozone (Raynor et al., 1996; Raynor et al., 1994; Wang et al., 2007). The aim of the present review is to discuss the roles played by opioid receptors, their agonists and antagonists in health and disease conditions.

**Uses of opioids:** Opioids have long been used to treat acute pain, such as post-operative pain (Raynor et al., 1994). They are commonly prescribed, and used, because of their effective analgesic properties. Studies have shown that properly managed medical use of opioid analgesic compounds is safe and rarely causes addiction. Taken exactly as prescribed, opioids can be used to manage pain effectively. They have also been found to be invaluable in palliative care to alleviate the severe, chronic and disabling pain of terminal conditions such as cancer and AIDS (Doyle et al., 2004). Contrary to popular belief, high doses are not required to control the pain of advanced or end-stage disease. In recent years there has been an increased use of opioids in the management of non-malignant chronic pain. This practice has grown from over 30 years experience in palliative care of long-term use of strong opioids, which has shown that dependence is rare when the drug is being used for pain relief (Doyle et al., 2004).

In addition to analgesia, clinical uses of opioids include codeine and hydrocodone for cough, natural opioids for diarrhoea, oxymorphone for anxiety due to shortness of breath and methadone and buprenorphine for heroin detoxification and maintenance programs during heroin replacement therapy (Eap et al., 1999, 2002). Despite the fact that opioids have been extensively reported to have psychological benefits, they are never officially prescribed to treat psychological illnesses, even in circumstances where researchers have reported opioids to be especially effective for example in the treatment of senile dementia, geriatric depression, and psychological distress due to chemotherapy or terminal diagnosis (Berridge, 2006).

Doyle et al. (2004) have shown that opioids are used to treat pain of moderate or greater severity, irrespective of the underlying pathophysiological mechanism. Morphine has been used to treat breathlessness of which several mechanisms have been suggested for its action. Codeine and loperamide are the most widely used opioids for diarrhoea. Loperamide has the advantage of acting only on the gut, since very little is absorbed and topical morphine in an aqueous gel can be an effective agent for treatment of painful wounds. Their use is based on the discovery of activated opioid receptors in damaged tissue (Doyle et al., 2004). Opioid medications can affect regions of the brain, resulting in the initial euphoria that many opioids produce. They can also produce drowsiness, because constipation and depending upon the amount taken, depress breathing. When taken as a large single dose, opioids could cause severe respiratory depression or death (Wang et al., 2007).

**Opioid receptor activation:** Milligan (2004) has shown that the opioid receptors form homomeric as well as heteromeric receptor complexes. Opioid receptors are capable of forming a heterodimer with each other and certain non-opioid receptors, for example, mu with alpha_2-adrenoceptors (Devi, 2001). This heterodimerisation between opioid receptors has been shown to result in changes in the pharmacology of the receptors as well as changes in receptor coupling to second messengers and trafficking (Corbett et al., 2006). It has been shown that both mu and delta receptors internalise on exposure to agonists, whereas kappa...
receptors do not and when such dimers such as delta/kappa dimers are formed, the trafficking properties of the kappa receptor predominates, while the heterodimer does not internalise on exposure to agonists of either receptors (Corbett et al., 2006; Koch and Hollt, 2008). Opioid receptor subtypes have been proposed largely on the basis of radioligand binding studies and as such there is little or no evidence for the presence of the different genes encoding these subtypes but in some cases, receptor heterodimerisation of opioid receptors has been proposed as a possible explanation (Corbett et al., 2006). Table 1 shows some of the agonists and antagonists of the opioid receptor subtypes.

All of the opioid receptors are GPCRs and couple to their cellular effectors primarily through G<sub>i</sub>/G<sub>o</sub> proteins, and thus the majority of opioid responses are pertussis toxin-sensitive (Milligan and Kostenis, 2006). Corbett et al. (2006) have shown that the different behaviours mediated by each of the receptor subtype in the intact animal such as euphoria for mu and dysphoria for kappa, result not from each type of receptor evoking different cellular responses but from the different anatomical distributions of each receptor (Corbett et al., 2006). Although the predominant action of opioids in the nervous system is inhibitory, in several brain regions such as Periaqueductal Grey (PAG), important for supraspinal analgesia or ventral tegmental area (VTA), for euphoria/reward, opioids are excitatory (Corbett et al., 2006). It has been shown that opioid-induced excitations are due, not to a direct excitatory action of opioids, but to disinhibition (Corbett et al., 2006). The apparent excitation of a neuron by opioids is as a result of inhibition of the release of inhibitory neurotransmitters such as Gamma Amino Butyric Acid (GABA) from the interneurons into the cell (Corbett et al., 2006).

Opioids have been shown to act via receptors interacting with heterotrimeric pertussis toxin (PTX) sensitive G proteins. The mu-selective agonist, DAMGO, and the delta-selective agonist, [D-Pen<sub>2</sub>,D-Pen<sub>3</sub>]-enkephalin (DPDPE) stimulated the incorporation of the photo-reactive GTP analogue into proteins co-migrating with the alpha subunits of G<sub>1</sub>, G<sub>2</sub>, G<sub>3</sub>, G<sub>12</sub>, and G<sub>13</sub> in the membranes of neuroblastoma SH-SY5Y cells while in the membranes of PTX-treated cells, both agonists were ineffective, because mu and delta opioid receptors appear to discriminate between PTX-sensitive G proteins which lead to activation of distinct G protein subtypes (Laugwitz et al., 1993). Subtype-specific immunoprecipitation of G protein alpha subunits photo-labelled in the absence or presence of agonists revealed profound differences between mu and delta opioid receptors in coupling to PTX-sensitive G proteins (Milligan, 2004).

Opioid inhibition of neuronal excitability resulting in the down-regulation of pain occurs largely by activation of potassium channels in the plasma membrane (Samways and Henderson, 2006). Opioid receptors are now known to activate a variety of potassium channels, including G-protein-activated inwardly rectifying (GIRK), calcium-activated inwardly rectifying, dendrotoxin-sensitive and M-type channels (Williams et al., 2001). Opioid receptors have been shown to inhibit high threshold voltage-activated calcium channels, like other members of the G<sub>i</sub>/G<sub>o</sub>-coupled receptor family such as cannabinoid (CB<sub>1</sub>) receptors (Corbett et al., 2006). In some cell types, such as neuronal cells, opioid receptor activation can also cause an elevation of the free calcium concentration inside cells by releasing calcium from intracellular stores or by enhancing calcium entry by a dihydropyridine-sensitive mechanism (Samways and Henderson, 2006). It has been shown that the activation of opioid receptors stimulates a variety of intracellular signalling mechanisms including activation of inwardly rectifying potassium channels, and inhibition of both voltage-operated N-type Ca<sup>2+</sup> channels and adenylyl cyclase activity (Samways and

multiple G-protein subtypes with similar potency used agonists of these receptors can activate and kappa-opioid receptors, suggesting that commonly ovary cell membranes, which agrees with studies on delta-potencies by mu receptor agonists in Chinese-hamster different G-proteins can be activated with different (Corbett back to the plasma membrane in a re-sensitised state whereas mu receptors are trafficked into endosomes, trafficked into lysosomes and are down-regulated, agonist activation (Corbett et al, 2006). Delta receptors are rapidly concentrated in clathrin-coated pits and undergo dynamin-dependent internalisation into early endosomes (Corbett et al, 2006). Delta receptors are trafficked into lysosomes and are down-regulated, whereas mu receptors are trafficked into endosomes, where they are dephosphorylated and recycled back to the plasma membrane in a re-sensitised state (Corbett et al, 2006). Thus, for mu receptor, internalisation can be considered to be involved in re-sensitisation, but not in desensitisation and there is evidence that different C-terminus splice variants of the mu receptor re-sensitise at different rates while the kappa receptors do not appear to internalise in response to agonist activation (Corbett et al, 2006).

Chakrabarti et al. (1995) have suggested that different G-proteins can be activated with different potencies by mu receptor agonists in Chinese-hamster ovary cell membranes, which agrees with studies on delta- and kappa-opioid receptors, suggesting that commonly used agonists of these receptors can activate multiple G-protein subtypes with similar potency (Burford et al., 2000). Carter and Medzihradsky (1993) have shown that mu-selective agonist, DAMGO inhibited cAMP formation in membranes of human neuroblastoma cells (SH-SY5Y), differentiated with retinoic acid. Antibodies to G alpha 1, 2 or G alpha 3 reduced the mu-opioid signal insignificantly and inhibition of adenyl cyclase by the delta-opioid agonist (DPDPE) was very sensitive to the G alpha 1, 2 antibodies (Carter and Medzihradsky, 1993).

Interaction of opioids and cannabinoids: Opioids and cannabinoids are among the most widely consumed drugs of abuse in the world (Manzanares et al., 1999; Smart and Ogborne, 2000). Both drugs have been shown to share some pharmacological properties including antinociception, hypothermia, sedation, hypotension, inhibition of both intestinal motility and locomotor activity (Manzanares et al., 1999). It has been reported that there is a cross-tolerance or mutual potentiation of these pharmacological effects. These phenomena have supported the possible existence of functional linkage in the mechanisms of action of both drugs especially in antinociception and drug addiction (Manzanares et al., 1999; Manzanares et al., 2005).

The cannabinoid and opioid compounds mimic endogenous ligands and act through the GPCRs, cannabinoid and opioid receptors (Felder and Glass, 1998; Kieffer, 1995). It has been shown that chronic administration of Δ⁹-THC increases opioid gene expression while, acute administration of Δ⁹-THC increases extracellular levels of endogenous enkephalins in the nucleus accumbens of mice (Corchero et al., 1997; Valverde et al., 2001). Some studies have also demonstrated the existence of cross-tolerance between opioid and cannabinoid agonists and such, morphine-tolerant animals show decreased Δ⁹-THC antinociceptive responses, whereas Δ⁹-THC-tolerant rodents show a decrease in morphine antinociception (Thorat and Bhargava, 1994; Ghozland et al., 2002). There is cross-dependence between opioid and cannabinoid compounds and opioid antagonist naloxone precipitated a withdrawal syndrome in Δ⁹-THC-tolerant rats, whereas cannabinoid antagonist SR171416A was able to precipitate abstinence in morphine-dependent rats (Navarro et al., 1998; Ghozland et al., 2002). The severity of opioid withdrawal was reduced by the administration of Δ⁹-THC or anandamide(Vela et al., 1995; Valverde et al., 2001). This bidirectional cross-dependence was confirmed by using knock-out mice and opioid dependence was reduced in mice lacking the CB1 receptor whereas, cannabinoid dependence was reduced in mice lacking the preproenkephalin gene (Ledent et al., 1999; Valverde et al., 2000).

Cannabinoids produce their rewarding effects by stimulating mesolimbic dopaminergic transmission which
has been shown to be a common substrate for the rewarding effects of other substances of abuse (Tanda et al., 1997). The activation of mu-opioid receptors could be involved in the bidirectional interaction between the endogenous cannabinoid and opioid systems in reward that extends to central mechanisms underlying relapsing phenomena (Fattore et al., 2004). This is because the endogenous cannabinoid system participates in the rewarding effects of opioids (Ghozland et al., 2002), and both morphine self-administration and place preference are decreased in mice lacking the CB1 receptors (Ledent et al., 1999; Martin et al., 2000). The possible involvement of the endogenous opioid system in the different motivational responses induced by cannabinoids is not yet well understood, however, GABAergic and corticotrophin-releasing factor systems, have been suggested to be involved in the anxiogenic responses induced by cannabinoids and these anxiogenic behaviours could have some influence in the dysphoric effects of cannabinoids (Rodriguez de Fonseca et al., 1996; Ghozland et al., 2002).

Ghozland et al. (2002), have shown that the disruption of mu-, delta-, or kappa-opioid receptor gene does not modify acute Δ9-THC responses while the expression of Δ9-THC withdrawal, and the development of Δ9-THC tolerance is only slightly altered in Kappa Opioid Receptor (KOR) knockout mice. Both mu- and kappa-opioid ligands have been reported to modulate cannabinoid antinociception (Manzanares et al., 1999). The Δ9-THC antinociception was blocked in mice by the kappa-selective opioid antagonist naltrexone (Smith et al., 1998; Ghozland et al., 2002). The synergistic effects of morphine and Δ9-THC on antinociception were also blocked by naltrexol or morphine and high doses of opioid antagonists are usually required to block Δ9-THC antinociception (Manzanares et al., 1999). Laboratory reports have shown that kappa receptors could contribute to the development of adaptive responses to chronic Δ9-THC administration, in agreement with the demonstration of cross-tolerance between Δ9-THC and kappa-opioid agonists (Smith et al., 1994).

A non-selective opioid antagonist naltrexone, precipitates an opioid-like withdrawal syndrome in cannabinoid-dependent rodents while, the CB1 cannabinoid receptor antagonist SR 141716A induces withdrawal in morphine-dependent rats (Navarro et al., 1998). This suggests that simultaneous activation of the two endogenous systems could participate in both opioid and cannabinoid dependence (Ghozland et al., 2002; Manzanares et al., 2005). Pre-treatment with Δ9-THC and anandamide, have been shown to decrease morphine withdrawal (Valverde et al., 2001), and the morphine-induced rewarding effects were suppressed in mice deficient in CB1 cannabinoid receptors, suggesting a bidirectional influence of µ-opioid and CB1 receptors on reward processes (Ledent et al., 1999; Ghozland et al., 2002).

Ghozland et al. (2002), have proposed that the opposing µ-opioid and κ-opioid receptor activities mediate the dual euphoric-dysphoric effects of Δ9-THC and a possible mechanism for this could be that cannabinoid receptor activation modifies endogenous opioid peptide levels in mesolimbic areas, that would in turn, modulate dopaminergic activity (Viganò et al., 2005). The release of opioid peptides by cannabinoids or endocannabinoids by opioids and their interactions at the level of receptor and their signal transduction mechanisms supports the finding of increased opioid peptide levels in the hypothalamus after cannabinoid treatment (Corchero et al., 1997; Viganò et al., 2005).

Cannabinoids and opioids can also interact at the level of their signalling activities. This is because reports have shown that both cannabinoid and opioid receptor types are coupled to similar intracellular effectors via Galpha-proteins, modulating cAMP levels, K+ and Ca2+ channel activities, and MAP kinase phosphorylation (Bouaboula et al., 1995; Fukuda et al., 1996; Manzanares et al., 1999). Viganò et al. (2005) studied the mechanism of cross-modulation between cannabinoid and opioid systems for analgesia during acute and chronic exposure. The result showed that acute co-administration of ineffectual sub-analgesic doses of synthetic cannabinoid CP-55,940 and morphine resulted in significant antinociception whereas, in rats made tolerant to CP-55,940, morphine challenge did not produce any analgesic response. The result of Viganò et al. (2005) study also showed alterations in the cAMP system, which seem to mirror the behavioural responses, indicating that the two systems may interact at the post receptor level which might open-up new therapeutic opportunities for relief of chronic pain through cannabinoid-opioid co-administration.

CONCLUSION

Opioid receptors and their agonists have long been involved in the treatment of acute pain such as post-operative pain. They are generally prescribed and used due to their effective analgesic properties and when properly managed the medical use of opioid analgesic compounds is safe and do not cause addiction. They are found to be invaluable in palliative care to alleviate severe, chronic and disabling pain of terminal conditions such as cancer and AIDS. Opioid use has increased over time in the management of non-malignant chronic pain and clinical uses of opioids include for cough, diarrhoea,
anxiety, heroin detoxification and maintenance programs during heroin replacement therapy. Opioids have been shown to be especially effective in the treatment of senile dementia, geriatric depression, and psychological distress due to chemo therapy or terminal diagnosis. Opioids receptors and their agonists are used to treat pain of moderate and greater severity, irrespective of the underlying pathophysiological mechanism.

ACKNOWLEDGMENT

The authors graciously acknowledge Queen Margaret University, Edinburgh for the award of the Martlet research fellowship and the Ahmadu Bello University Zaria-Nigeria for awarding the first author study fellowship to undertake this research studies.
